

TSSL Lab 4 - Recurrent Neural Networks

In this lab we will explore different RNN models and training procedures for a problem in time series prediction.

In [1]:

```
import numpy as np
import tensorflow as tf
from tensorflow import keras
from tensorflow.keras import layers
import pandas
import matplotlib.pyplot as plt

plt.rcParams["figure.figsize"] = (10,6) # Increase default size of plots
```

Set the random seed, for reproducibility

In [2]:

```
np.random.seed(42)
tf.random.set_seed(42)
```

1. Load and prepare the data

We will build a model for predicting the number of [sunspots](#). We work with a data set that has been published on [Kaggle](#), with the description:

Sunspots are temporary phenomena on the Sun's photosphere that appear as spots darker than the surrounding areas. They are regions of reduced surface temperature caused by concentrations of magnetic field flux that inhibit convection. Sunspots usually appear in pairs of opposite magnetic polarity. Their number varies according to the approximately 11-year solar cycle.

The data consists of the monthly mean total sunspot number, from 1749-01-01 to 2017-08-31.

In [3]:

```
# Read the data
data=pandas.read_csv('Sunspots.csv',header=0)
dates = data['Date'].values
y = data['Monthly Mean Total Sunspot Number'].values
ndata=len(y)
print(f'Total number of data points: {ndata}')

# We define a train/test split, here with 70 % training data
ntrain = int(ndata*0.7)
ntest = ndata-ntrain
print(f'Number of training data points: {ntrain}')
```

Total number of data points: 3252
Number of training data points: 2276

In [4]:

```
plt.plot(dates[:ntrain], y[:ntrain])
plt.plot(dates[ntrain:], y[ntrain:])
plt.xticks(range(0, ndata, 300), dates[::300], rotation = 90); # Show only one tick
```

There is a clear seasonality to the data, but the amplitude of the peaks very quite a lot. Also, we note that the data is nonnegative, which is natural since it consists of counts of sunspots. However, for simplicity we will not take this constraint into account in this lab assignment and allow ourselves to model the data using a Gaussian likelihood (i.e. using MSE as a loss function).

From the plot we see that the range of the data is roughly [0,400] so as a simple normalization we divide by the constant `MAX_VAL=400`.

In [5]:

```
MAX_VAL = 400
y = y/MAX_VAL
```

2. Baseline methods

Before constructing any sophisticated models using RNNs, let's consider two baseline methods,

1. The first baseline is a "naive" method which simply predicts $y_t = y_{t-1}$.
2. The second baseline is an AR(p) model (based on the implementation used for lab 1).

We evaluate the performance of these method in terms of mean-squared-error and mean-absolute-error, to compare the more advanced models with later on.

In [6]:

```
def evaluate_performance(y_pred, y, split_time, name=None):
    """This function evaluates and prints the MSE and MAE of the prediction.

    Parameters
    -----
    y_pred : ndarray
        Array of size (n,) with predictions.
    y : ndarray
        Array of size (n,) with target values.
    split_time : int
        The leading number of elements in y_pred and y that belong to the training data.
        The remaining elements, i.e. y_pred[split_time:] and y[split_time:] are treated as test data.

    Returns
    -----
    mse : float
        Mean squared error between y and y_pred.
    mae : float
        Mean absolute error between y and y_pred.
    """
    if name is None:
        name = "None"
    print(f"Evaluating {name} performance...")
    mse = np.mean((y - y_pred) ** 2)
    mae = np.mean(np.abs(y - y_pred))
    print(f"Mean Squared Error: {mse:.2f}")
    print(f"Mean Absolute Error: {mae:.2f}")

    return mse, mae
```

```

    .....

    # Compute error in prediction
    resid = y - y_pred

    # We evaluate the MSE and MAE in the original scale of the data, i.e. we add back
    train_mse = np.mean(resid[:split_time]**2)*MAX_VAL**2
    test_mse = np.mean(resid[split_time:])**2)*MAX_VAL**2
    train_mae = np.mean(np.abs(resid[:split_time]))*MAX_VAL
    test_mae = np.mean(np.abs(resid[split_time:]))*MAX_VAL

    # Print
    print(f'Model {name}\n  Training MSE: {train_mse:.4f},   MAE: {train_mae:.4f}\n'

```

Q1: Implement the naive baseline method which predicts according to $\hat{y}_{t|t-1} = y_{t-1}$. Since the previous value is needed for the prediction we do not get a prediction at $t = 1$. Hence, we evaluate the method by predicting values at $t = 2, \dots, n$ (cf. an AR(p) model where we start predicting at $t = p + 1$).

In [7]:

```

# Store the predictions in an array of length ndata-1. Note that there is a shift in
# between the prediction and the observation sequence, since there is no prediction
# Specifically, y_pred_naive[t] is a prediction of y[t+1], so the first element of y
# second element of y, and so on. We will use the same "bookeeping convention" through
# you understand it!
y_pred_naive = y[:-1]

evaluate_performance(y_pred_naive, # Predictions
                     y[1:],      # Corresponding target values
                     ntrain-1,    # Number of leading elements in the input array
                     name='Naive')

```

Model Naive
 Training MSE: 776.5437, MAE: 19.3285
 Testing MSE: 708.6360, MAE: 19.2256

Next, we consider a slightly more advanced baseline method, namely an AR(p) model.

In [8]:

```

# We import two functions that were written as part of Lab 1
from tssltools_lab4 import fit_ar, predict_ar_1step

p=30 # Order of the AR model (set by a few manual trials)
ar_coef = fit_ar(y[:ntrain], p) # Fit the model to the training data

# Predict. Note that y contains both training and validation data,
# and the prediction is for the values y_{p+1}, ..., y_n.
y_pred_ar = predict_ar_1step(ar_coef, y)

```

In [9]:

```

evaluate_performance(y_pred_ar, # The prediction array is of length n-p
                     y[p:],      # Corresponding target values
                     ntrain-p,    # Number of leading elements in the input arrays
                     name='AR')

```

Model AR
 Training MSE: 603.8656, MAE: 17.3420
 Testing MSE: 590.3732, MAE: 17.6221

3. Simple RNN

We will now construct a model based on a recurrent neural network. We will initially use the `SimpleRNN` class from *Keras*, which correspond to the basic Jordan-Elman network presented in the lectures.

Q2: Assume that we construct an "RNN cell" using the call `layers.SimpleRNN(units = d, return_sequences=True)`. Now, assume that an array `X` with the dimensions $[Q, M, P]$ is fed as the input to the above object. We know that `X` contains a set of sequences (time series) with equal lengths. Specify which of the symbols Q, M, P that corresponds to each of the items below:

- The length of the sequences (number of time steps)
- The number of features (at each time step), i.e. the dimension of each time series
- The number of sequences

Furthermore, specify the values of Q, M, P for the data at hand (treated as a single time series).

Hint: Read the documentation for [SimpleRNN](#) to find the answer.

A2:

`Q - n M - 1 P - 1`

Q3: Continuing the question above, answer the following:

- What is the meaning of setting `units = d`?
- Assume that we pass a single time series of length n as input to the layer. Then what is the dimension of the *output*?
- If we would had set the parameter `return_sequences=False` when constructing the layer, then what would be the answer to the previous question?

A3:

- `units` : Positive integer, dimensionality of the output space.
- `[1, n, 1]`
- `[1, 1]`

In *Keras*, each layer is created separately and are then joined by a `Sequential` object. It is very easy to construct stacked models in this way. The code below corresponds to a simple Jordan-Elman Network on the form,

$$\mathbf{h}_t = \sigma(W\mathbf{h}_{t-1} + Uy_{t-1} + b), \\ \hat{y}_{t|t-1} = \mathbf{C}\mathbf{h}_t + c,$$

Note: It is not necessary to explicitly specify the input shape, since this can be inferred from the input on the first call. However, for the `summary` function to work we need to tell the model what the dimension of the input is so that it can infer the correct sizes of the involved matrices. Also note that in *Keras* you can sometimes use `None` when some dimensions are not known in advance.

In [10]:

```
d = 10 # hidden state dimension

model0=keras.Sequential([
    # Simple RNN Layer
    layers.SimpleRNN(units = d, input_shape=(None,1), return_sequences=True, activation='linear')
    # A Linear output layer
```

```

        layers.Dense(units = 1, activation='linear')
    ])

# We store the initial weights in order to get an exact copy of the model when trying
model0.summary()
init_weights = model0.get_weights().copy()

```

Model: "sequential"

Layer (type)	Output Shape	Param #
<hr/>		
simple_rnn (SimpleRNN)	(None, None, 10)	120
<hr/>		
dense (Dense)	(None, None, 1)	11
<hr/>		
Total params: 131		
Trainable params: 131		
Non-trainable params: 0		

Q4: From the model summary we can see the number of parameters associated with each layer. Relate these numbers to the dimensions of the weight matrices and bias vectors $\{W, U, b, C, c\}$ in the mathematical model definition above.

A4:

- W - [10,10] - 100
- U - [10,1] - 10
- b - [10,1] - 10
- C - [1,10] - 10
- c - [1,1] - 1

4. Training the RNN model

In this section we will consider a few different ways of handling the data when training the simple RNN model constructed above. As a first step, however, we construct explicit input and target (output) arrays for the training and test data, which will simplify the calls to the training procedures below.

The task that we consider in this lab is one-step prediction, i.e. at each time step we compute a prediction $\hat{y}_{t|t-1} \approx y_t$ which depend on the previous observations $y_{1:t-1}$. However, when working with RNNs, the information contained in previous observations is aggregated in the *state* of the RNN, and we will only use y_{t-1} as the *explicit input* at time step t .

Furthermore, when addressing a problem of time series prediction it is often a good idea to introduce an explicit skip connection from the input y_{t-1} to the prediction $\hat{y}_{t|t-1}$. Equivalently, we can *define the target value* at time step t to be the residual $\tilde{y}_t := y_t - \hat{y}_{t|t-1}$. Indeed, if the model can predict the value of the residual, then we can simply add back y_{t-1} to get a prediction of y_t .

Taking this into consideration, we define explicit input and output arrays as shifted versions of the data series $y_{1:n}$.

In [11]:

```

# Training data
x_train = y[:ntrain-1] # Input is denoted by x, training inputs are x[0]=y[0], ...
yt_train = y[1:ntrain] - x_train # Output is denoted by yt, training outputs are yt

```

```
# Test data
x_test = y[ntrain-1:-1] # Test inputs are x_test[0] = y[ntrain-1], ..., x_test[ntrain-1]
yt_test = y[ntrain:] - x_test # Test outputs are yt_test[0] = y[ntrain]-y[ntrain-1]

# Reshape the data
x_train = x_train.reshape((1,ntrain-1,1))
yt_train = yt_train.reshape((1,ntrain-1,1))
x_test = x_test.reshape((1,ntest,1))
yt_test = yt_test.reshape((1,ntest,1))
```

Option 1. Process all data in each gradient computation ("do nothing")

The first option is to process all data at each iteration of the gradient descent method.

In [12]:

```
model1 = keras.models.clone_model(model0) # This creates a new instance of the same
model1.set_weights(init_weights) # We set the initial weights to be the same for al
```

Q5: What should we set the *batch size* to, in order to compute the gradient based on the complete training data sequence at each iteration? Complete the code below!

Note: You can set `verbose=1` if you want to monitor the training progress, but if you do, please **clear the output of the cell** before generating a pdf with your solutions, so that we don't get multiple pages with training errors in the submitted reports.

In [13]:

```
model1.compile(loss='mse', optimizer='rmsprop', metrics=['mse'])
history = model1.fit(x_train, yt_train,
                      epochs = 200,
                      batch_size = 1,
                      verbose = 0,
                      validation_data = (x_test, yt_test))
```

We plot the training and test error vs the iteration (epoch) number, using a helper function from the `tssltools_lab4` module.

In [14]:

```
from tssltools_lab4 import plot_history
start_at = 10 # Skip the first few epochs for clarity
plot_history(history, start_at)
```

Q6: Finally we compute the predictions of $\{y_t\}$ for both the training and test data using the model's `predict` function. Complete the code below to compute the predictions.

Hint: You need to reshape the data when passing it to the `predict` to comply with the input shape used in Keras (cf. above).

Hint: Since the model is trained on the residuals \tilde{y}_t , don't forget to add back y_{t-1} when predicting y_t . However, make sure that you don't "cheat" by using a non-causal predictor (i.e. using y_t when predicting y_t)!

In [15]: *# Predict on all data using the final model.*

```
# We predict using y_1,...,y_{n-1} as inputs, resulting in predictions of the values
# That is, y_pred1 should be an (n-1,) array where element y_pred1[t] is based only on
y_pred1 = model1.predict(y[:-1].reshape((1,len(y)-1,1))).flatten() + y[:-1]
```

Using the prediction computed above we can plot them and evaluate the performance of the model in terms of MSE and MAE.

In [16]: *def plot_prediction(y_pred):*

```
# Plot prediction on test data
plt.plot(dates[ntrain:], y[ntrain:])
plt.plot(dates[ntrain:], y_pred[ntrain-1:])
plt.xticks(range(0, ntest, 300), dates[ntrain::300], rotation = 90); # Show only every 3rd tick
plt.legend(['Data', 'Prediction'])
plt.title('Predictions on test data')
```

In [17]: *# Plot prediction*

```
plot_prediction(y_pred1)

# Evaluate MSE and MAE (both training and test data)
evaluate_performance(y_pred1, y[1:], ntrain-1, name='Simple RNN, "do nothing"')
```

Model Simple RNN, "do nothing"

Training MSE: 617.8157, MAE: 17.8616

Testing MSE: 573.7734, MAE: 17.7223

Predictions on test data

Option 2. Random windowing

Instead of using all the training data when computing the gradient for the numerical optimizer, we can speed it up by restricting the gradient computation to a smaller window of consecutive time steps. Here, we sample a random window within the training data and "pretend" that this window is independent from the observations outside the window. Specifically, when processing the observations within each window the hidden state of the RNN is initialized to zero at the first time point in the window.

To implement this method in Python, we will make use of a *generator function*. A generator is a function that can be paused, return an intermediate value, and then resumed to continue its execution. An intermediate return value is produced using the `yield` keyword.

Generators are used in *Keras* to implement infinite loops that feed the training procedure with training data. Specifically, the `yield` statement of the generator should return a pair `x, y` with inputs and corresponding targets from the training data. Each epoch of the training procedure will then call the generator for a total of `steps_per_epoch` such `yield` statements.

In [18]:

```
def generator_train(window_size):
    while True:
        """The upper value is excluded in randint, so the maximum value that we can
        Hence, the maximum end point of a window is ntrain-1, in agreement with the
        when working with one-step-ahead prediction."""
        start_of_window = np.random.randint(0, ntrain - window_size) # First time index
        end_of_window = start_of_window + window_size # Last time index of window
        yield x_train[:,start_of_window:end_of_window,:], yt_train[:,start_of_window]
```

In [19]:

```
model12 = keras.models.clone_model(model0) # This creates a new instance of the same
```

```
model2.set_weights(init_weights) # We set the initial weights to be the same for all
```

Q7: Assume that we process a window of observations of length `window_size` at each iteration. Then, how many gradient steps per epoch can we afford, for computational cost per epoch to be comparable to the method considered in Option 1? Set the `steps_per_epoch` parameter of the fitting function based on your answer.

In [20]:

```
window_size = 100
model2.compile(loss='mse', optimizer='rmsprop', metrics=['mse'])
history = model2.fit(generator_train(window_size),
                      epochs = 200,
                      verbose = 0,
                      steps_per_epoch = int(ntrain/window_size),
                      validation_data = (x_test, yt_test))
```

Similarly to above we plot the error curves vs the iteration (epoch) number.

In [21]:

```
plot_history(history, start_at)
```

Q8: Comparing this error plot to the one you got for training Option 1, can you see any qualitative differences? Explain the reason for the difference.

A8: We can see an oscillating pattern for both the train error and test error. The training error reflects higher variance all over the Epoch domain, that can be due to the poor performance on some repeated variant data. On the other hand, test error it's being assessed over a fix sequence of data, reflecting less variance and more stability

Q9: Compute a prediction for all values of $\{y_2, \dots, y_n\}$ analogously to **Q6**.

In [22]:

```
# Predict on all data using the final model.
# We predict using  $y_1, \dots, y_{n-1}$  as inputs, resulting in predictions of the values
y_pred2 = model2.predict(y[:-1].reshape((1, len(y)-1, 1))).flatten() + y[:-1]
```

In [23]:

```
# Plot prediction on test data
```

```
plot_prediction(y_pred2)

# Evaluate MSE and MAE (both training and test data)
evalutate_performance(y_pred2, y[1:], ntrain-1, name='Simple RNN, windowing')
```

Model Simple RNN, windowing

Training MSE: 602.6192, MAE: 17.5562
 Testing MSE: 570.0144, MAE: 17.3017

Option 3. Sequential windowing with stateful training

As a final option we consider a model aimed at better respecting the temporal dependencies between consecutive windows. This is based on "statefulness" which simply means that the RNN remembers its hidden state between calls. That is, if model is in stateful mode and is used to process two sequences of inputs after each other, then the final state from the first sequence is used as the initial state for the second sequence.

In [24]:

```
# To enable stateful training, we need to create model where we set stateful=True in
model3=keras.Sequential([
    # Simple RNN layer with stateful=True
    layers.SimpleRNN(units = d, batch_input_shape=(1,None,1), return_sequences=True,
    # A Linear output Layer
    layers.Dense(1, activation='linear')
])
model3.set_weights(init_weights)
```

Q10: When working with stateful training we need to make some adjustments to the training data generator.

1. First, the RNN model doesn't keep track of the actual time indices of the different windows that it is fed. Hence, if we feed the model randomly selected windows, it will still treat them as if they were consecutive, and retain the state from one window to the next. To avoid this,

we therefore need to make sure that the generator outputs windows of training data that are indeed consecutive (and not randomly selected as above).

2. When training the model we will process the whole training data multiple times (i.e. we train for multiple epochs). However, if we have statefulness *between epochs* this would effectively result in a "circular dependence", where the final state at time step $t = n_{\text{train}}$ would be used as the initial state at time $t = 1$. To avoid this, we can manually reset the state of the model by calling `model.reset_states()`.

Taking this two points into consideration, complete the code for the stateful data generator below.

```
In [25]: def generator_train_stateful(window_size, model):
    """In addition to the window_size, the generator also takes the model as input so that we can reset the RNN states at appropriate intervals."""

    # Compute the total number of windows of Length window_size that we need to cover
    # Note 1. The length of x_train (and yt_train) is ntrain-1 since we work with 1D arrays
    # Note 2. The final window could be smaller than window_size, if (ntrain-1) is
    number_of_windows = int((ntrain)/ window_size)

    while True:
        for i in range(number_of_windows):
            # First time index of window (inclusive)
            start_of_window = i*window_size

            # Last time index of window (exclusive, i.e. this is the index to the first element)
            # Note 3. Python allows using end_of_window > ntrain-1, it will simply take the last element
            end_of_window = start_of_window + window_size

            yield x_train[:,start_of_window:end_of_window,:], yt_train[:,start_of_window:end_of_window]
            model.reset_states()

    """NOTE! In addition to replacing the ????? with the correct code, you need to move the code
    to the correct place in the function definition above!"""

```

With the generator defined we can train the model.

```
In [26]: window_size = 100
model3.compile(loss='mse', optimizer='rmsprop', metrics=['mse'])
history = model3.fit(generator_train_stateful(window_size, model3),
                      epochs = 200,
                      verbose = 0,
                      steps_per_epoch = ntrain//window_size,
                      validation_data = (x_test, yt_test))
```

Similarly to above we plot the error curves vs the iteration (epoch) number.

```
In [27]: plot_history(history, start_at)
```

Q11: Comparing this error plot to the one you got for training Options 1 and 2, can you see any *qualitative* differences?

Optional: If you have a theory regarding the reason for the observed differences, feel free to explain!

A11:

The downtrend of the training test is explained by the constant learning over contiguous sequential window steps. It behaves as monotonically decreasing except for one spike also experienced in the test error. Unlike in the former model, there's now oscillation observed. Additionally, the testing error experiences a starting decrease accompanying the train error in the learning but starts to overfit around the epoch N=70. Both lines look smoother as the training is performed over highly correlated window sequences

Q12: Compute a prediction for all values of $\{y_2, \dots, y_n\}$ analogously to **Q6**.

In [28]:

```
# Predict on all data using the final model.
# We predict using y_1,...,y_{n-1} as inputs, resulting in predictions of the values
y_pred3 = model3.predict(y[:-1].reshape((1,len(y)-1,1))).flatten() + y[:-1]
```

In [29]:

```
# Plot prediction on test data
plot_prediction(y_pred3)

# Evaluate MSE and MAE (both training and test data)
evalutate_performance(y_pred3, y[1:], ntrain-1, name='Simple RNN, windowing/stateful')
```

Model Simple RNN, windowing/stateful

Training MSE: 624.2744, MAE: 17.8855
Testing MSE: 615.4802, MAE: 18.0731

Predictions on test data

5. Reflection

Q13: Which model performed best? Did you manage to improve the prediction compared to the two baseline methods? Did the RNN models live up to your expectations? Why/why not? Please reflect on the lab using a few sentences.

A13:

- Testing MSE: 708.6360, MAE: 19.2256 naive
- Testing MSE: 590.3732, MAE: 17.6221 ar(30)
- Testing MSE: 573.7734, MAE: 17.7223 RNN
- Testing MSE: 570.0144, MAE: 17.3017 RNN with random windowing
- Testing MSE: 615.4802, MAE: 18.0731 Sequential windowing with stateful training RNN

RNN with random windowing performed best, test error is slightly smaller than AR(30) error. No, because improvement in the performance doesn't outweigh the complexity of the models. Computationally-wise, it wouldn't be recommended to use such complex models instead of the more basic one (ar(30), which is also better performant) as they have far more parameters to train compared to it and use more resources.

6. A more complex network (OPTIONAL)

If you are interested, feel free to play around with more complex models and see if you can improve the predictive performance! It is very easy to build stacked models in Keras, see the example below.

In [30]:

```
# A stacked model with 3 Layers of LSTM cells, two Dense Layers with Relu activation
model4 = tf.keras.models.Sequential([
    tf.keras.layers.LSTM(64, batch_input_shape=(1,None,1), return_sequences=True, stat
```

```

tf.keras.layers.LSTM(64, batch_input_shape=(1, None, 1), return_sequences=True, stat
tf.keras.layers.LSTM(64, batch_input_shape=(1, None, 1), return_sequences=True, stat
tf.keras.layers.Dense(32, activation="relu"),
tf.keras.layers.Dense(16, activation="relu"),
tf.keras.layers.Dense(1),
])
model4.summary()

```

Model: "sequential_2"

Layer (type)	Output Shape	Param #
lstm (LSTM)	(1, None, 64)	16896
lstm_1 (LSTM)	(1, None, 64)	33024
lstm_2 (LSTM)	(1, None, 64)	33024
dense_2 (Dense)	(1, None, 32)	2080
dense_3 (Dense)	(1, None, 16)	528
dense_4 (Dense)	(1, None, 1)	17

Total params: 85,569
Trainable params: 85,569
Non-trainable params: 0

We can store the best model in a file, so that we can load it after analysing the training procedure.

In [31]:

```

checkpoint_filepath = './'
model_checkpoint_callback = tf.keras.callbacks.ModelCheckpoint(
    filepath=checkpoint_filepath,
    save_weights_only=True,
    monitor='val_loss',
    save_best_only=True) # Save only the best model, determined by the validation loss

```

Train the model

In [32]:

```

window_size = 100
model4.compile(loss='mse', optimizer='rmsprop', metrics=['mse'])
history = model4.fit(generator_train_stateful(window_size, model4),
                      epochs = 200,
                      verbose = 0,
                      steps_per_epoch = ntrain//window_size,
                      validation_data = (x_test, yt_test),
                      callbacks=[model_checkpoint_callback])

```

In [33]:

```
plot_history(history, start_at)
```

Q14 (optional): Based on the training and test error plots, are there signs of over- or underfitting?

A14:

model overfits at about 40 epochs. sign - test error increases while training error decreases.

We load the best model from checkpoint.

```
In [34]: model4.load_weights(checkpoint_filepath)
```

```
Out[34]: <tensorflow.python.training.tracking.util.CheckpointLoadStatus at 0x18e8bf121c0>
```

```
In [35]: # Predict on all data using the final model.  
# We predict using  $y_1, \dots, y_{n-1}$  as inputs, resulting in predictions of the values  
y_pred4 = model4.predict(y[:-1].reshape(1, ntrain-1, 1)).flatten() + y[:-1]
```

```
In [36]: # Plot prediction on test data  
plot_prediction(y_pred4)  
  
# Evaluate MSE and MAE (both training and test data)  
evalutate_performance(y_pred4, y[1:], ntrain-1, name='Stacked RNN, windowing/statefu
```

Model Stacked RNN, windowing/stateful
Training MSE: 632.1048, MAE: 18.0754
Testing MSE: 559.5319, MAE: 17.4821

Predictions on test data
